About the Organizations Involved in this Report

The Institute for Clinical Evaluative Sciences

The Institute for Clinical Evaluative Sciences (ICES) is an independent, non-profit organization that uses population-based health information to produce knowledge on a broad range of health care issues. ICES' unbiased evidence provides measures of health system performance, a cleaner understanding of the shifting health care needs of Ontarians, and a stimulus for discussion of practical solutions to optimize scarce resources.

Key to ICES' work is its ability to link population-based health information, at the patient level, in a way that ensures the privacy and confidentiality of personal health information. Linked databases reflecting 13 million of 34 million Canadians allow researchers to follow patient populations through diagnosis and treatment, and to evaluate outcomes.

ICES receives core funding from the Ontario Ministry of Health and Long-Term Care. In addition, ICES scientists and staff compete for peer-reviewed grants from federal funding agencies, such as the Canadian Institutes of Health Research, and receive project-specific funds from provincial and national organizations. ICES' knowledge is highly regarded in Canada and abroad, and is widely used by government, hospital, planners, and practitioners to make decision about health care delivery and to develop policy.

The Ottawa Hospital Research Institute

The Ottawa Hospital Research Institute is the research arm of The Ottawa Hospital and an affiliated institute of the University of Ottawa, closely associated with the university's Faculties of Medicine and Health Sciences. OHRI includes more than 1,700 scientists, clinical investigators, graduate students, postdoctoral fellows and staff conducting research to improve the understanding, prevention, diagnosis and treatment of human disease.

Background

Smoking, unhealthy alcohol consumption, poor diet and physical inactivity play an important role in overall health. Previously, our research team at the Institute for Clinical Evaluative Sciences (ICES) examined the impact of these four health behaviours on hospitalization costs. The *900,000 Days in Hospital report* demonstrated that 32% of hospital bed-days between 2001 and 2012 were attributable to these behaviours.¹

Ontario policy makers and public health practitioners are interested in the broader impact of health behaviours on health care use—the focus of this report. This study is in response to requests^a to provide

further insights into the health care system and both the potential economic and health equity impacts of preventive strategies.

Breaking New Ground

The study uses unique Canadian data that individually link respondents from a large population health survey, the Canadian Community Health Survey, to a wide range of health care data in Ontario. These data provide

the largest and most complete examination of the relationship between health behaviours and health care costs. To our knowledge, this study is the first to directly measure how changes in health behaviours have resulted in increased or decreased health care use. We examined the following questions:

1. What are the direct health care costs associated with smoking, unhealthy alcohol consumption, poor diet and physical inactivity?
2. What has been the change in direct health care costs as a consequence of recent improvements in or worsening of health behaviours?

^a Requests for information submitted through the Applied Health Research Question (AHRQ) initiative of the Ontario Ministry of Health and Long-Term Care by a health-system policy maker or care provider seeking research evidence that will inform planning, policy and program development for the benefit the entire Ontario health system.

3. What are the direct health care costs associated with socioeconomic position (i.e., education, family income, home ownership and neighbourhood deprivation)
4. What is the health care cost for Ontarians who have healthy versus unhealthy behaviours and high versus low socioeconomic position?

Measurements of Health Care Costs

Our study examined a cohort of individuals surveyed between 2003 and 2008. We followed each individual for four years between 2004 and 2013 to examine his or her total health care costs, as well as health care costs across three sectors:

- **Hospital care.** We combined costs from inpatient hospitalizations, same-day surgeries, emergency department visits, and stays in rehabilitation hospitals and complex continuing care centres.
- **Drugs.** For Ontarians aged 65 and older, Ontario Drug Benefit costs were captured.
- **Community care.** We combined costs from primary care billings, specialist billings, laboratory billings, capitation services and home care services.

Methods

Data Sources

We examined the relationship between behavioural risks and health care costs using the Ontario sample of three population health surveys: the Canadian Community Health Survey (CCHS) cycles 2.1, 3.1 and 4.1 (conducted in 2003, 2005 and 2007–2008, respectively). The CCHS is a cross-sectional survey conducted by Statistics Canada that collects data related to health determinants, health status and health care use. The survey employs a complex, multistage sampling strategy to randomly select households in each health region. Individuals in each household are automatically selected to participate in the survey

using various selection probabilities based on age and household composition. A weight is assigned to each respondent signifying the number of individuals the respondent represents in the target population. The target population includes individuals aged 12 and older living in Canada's ten provinces and three territories. Individuals living on First Nations reserves, institutionalized residents, full-time members of the Canadian Forces and residents of certain remote areas are excluded from the survey's coverage.

The Ontario sample of the three CCHS cycles conducted between 2003 and 2008 provided 128,501 valid interviews. Of these respondents, a subset agreed to share and link their interview information. In total, 101,506 respondents were successfully linked to their Ontario Health Insurance Plan (OHIP) number

using a deterministic and probabilistic algorithm. For our study, respondents were included if they were eligible for publicly funded health care from OHIP, not pregnant at the time of survey administration, and aged 25 and older. For individuals with multiple interviews, only the earliest interview was included. We excluded respondents who were lost to follow-up in the first year following their interview (i.e., they were not available at the beginning of the study). This resulted in a final cohort of 80,749 unique Ontario respondents (**Exhibit A-1** in the Appendix). These individuals were followed for up to four years beginning one year after survey administration.

Direct health care cost data at ICES

The CCHS respondents were individually linked to all records of health care use that was paid for by the Ministry of Health and Long-Term Care (MOHLTC). The cost associated with each record was estimated using costing methods developed for health administrative data.² Briefly, a payer (the MOHLTC) costing perspective was taken, using person-level health care utilization data and per-use fee information or budgetary data. Cost information for sectors (i.e., acute hospitalization, same-day surgery, emergency department, inpatient rehabilitation and complex continuing care) that are funded using global budgets (e.g., by institution) are determined using a top-down approach through case-mix methodology. Sectors that have fee payments associated with each use (e.g., prescription drugs, physician services and home care) have costs estimated directly. All costs were expressed in 2014 Canadian dollars; we inflated past costs using the annual general Consumer Price Index reported by Statistics Canada.

Behavioural and other risk factors for health care use

Exhibit 1 and **Exhibit A-2** in the Appendix present the health behaviours (smoking, alcohol consumption, diet and physical activity) and other risks that were examined for their association with health care use.

Other risks include age, sex, stress, preventive health behaviour (flu vaccination), sociodemographic factors (immigrant status, education level, urban dwelling, neighbourhood deprivation, household income, home ownership, marital status), health status indicators (body mass index, hypertension, diabetes, heart disease, cancer, history of stroke, dementia, and extent of difficulty in performing basic tasks or participating in activities).

Public health care spending data

A number of health care costs were not included in our primary analysis. In addition to the costs that were excluded either by design (e.g., long-term care and mental health care costs) or due to limitations with the data (e.g., outpatient clinic visits in hospital settings), expenditures^b to operate the health care system (e.g., MOHLTC administration) and capital costs for large-scale projects (e.g., building new hospitals) are not reflected in the person-level costs. To account for these exclusions in our cost analysis, we obtained annual total health care costs from publicly available Ontario Ministry of Finance records from 2003/04 to 2013/14.³⁻¹⁵ The costs from each year were divided into our three health care sectors; costs that did not align with any of the three sectors were assigned to an 'other' category.

Not included in this study are costs incurred outside of the health care system, such as lost productivity, wages and income related to illness associated with

unhealthy living, or costs borne by individuals to care for their illness (referred to as indirect costs). Also not included are costs for health care beyond those paid by the MOHLTC (e.g., employee health plans).

Analyses

Development of multivariable risk models

CCHS respondents were tracked for their health care use over a four-year follow-up period starting one year after survey administration. For acute care and rehabilitation hospitalizations that extended beyond the follow-up period, a proportion of the costs were included based on the length of stay that fell within the follow-up period.

We developed multivariable models to estimate the effect of health behaviours on health care costs. When building the models, we sought to address three main considerations in attributing health behaviours to health care:

- First, appropriate adjustment for other risk factors for increased costs, such as age and sociodemographic factors that are correlated with health behaviours.
- Second, consideration of the role of factors such as body mass index, blood pressure and health

^b In this case, expenditure by the health care system is defined as the cost to the system of the inputs required to treat, for example, a smoking-related disease. Thus, we use the terms cost and expenditure interchangeably.

behaviour-related disorders that may mediate the relationship between health behaviours and health care costs. The concern was that including these risks in a multivariable model may inappropriately attenuate (lower) the risk from health behaviours.

- Third, consideration of pre-existing illness that may have led to health behaviour changes. For example, as people become ill and frail, they may become less physically active. In such a situation, physical inactivity may be associated with increased health care cost that is more appropriately identified as illness-associated inactivity.

We created separate, sex-specific, generalized linear models with a negative binomial distribution for each of the health care sectors: hospital care, drugs and community care. The models employed an offset to adjust for differences in follow-up between respondents. The models were created using a prespecified, stepwise approach that started with a *health behaviour model* followed by a basic *sociodemographic model*, a *primary attribution model* that adjusted for additional sociodemographic factors, a *distal mediator model* that included health status indicators, and a *proximal mediator model* that included a measure of fragility (**Exhibit A-2** in the Appendix). This stepwise analysis resulted in 15 models for each sex (**Exhibits A-12 to A-17** in the Appendix).

Population attributable fractions of cost to health behaviours and socioeconomic position

The proportion of the health care cost burden that can be attributed to health behaviours—the population attributable fraction (PAF)—was calculated from 2003/04 to 2013/14 for each health care sector.

Annual PAFs were estimated using the corresponding CCHS cycle or, for years between CCHS cycles, by averaging the PAFs from the preceding and succeeding years. PAF calculations were performed using a risk factor-deleted approach. In the first step, the expected annual health care costs of the population for a specific sector were estimated by applying the corresponding sector-specific primary attribution models to the weighted CCHS cycle. In the second step, the calculation was repeated after recoding each respondent's health behaviour to the counterfactual reference or "no exposure" category. For example, we first estimated the hospital costs of the weighted cohort for all smoking exposures (i.e., current, former and non-smokers), and then re-estimated the hospital costs of the weighted cohort assuming all current and former smokers were non-smokers. The difference between the two calculations created an estimate of the annual contribution of smoking to hospital costs. In the final step, this difference was divided by the original population estimate (from the first step) to produce a population attributable fraction. In our example, this would be the PAF of hospital costs to smoking. Health sector specific PAFs were calculated for each health behaviour, and the combination of health behaviours.

The same analysis was performed for different socioeconomic groups defined by education level, family income, home ownership and neighbourhood deprivation. The equity gap in health care use was defined as the difference in cost between socioeconomic groups. Meaning, we calculated expected health care costs if all Ontarians were at the socioeconomic category with the lowest health care costs (e.g., the cost for people with post-secondary education or the highest family income).

Costs attributable to individuals with different health behaviours and socioeconomic position

We estimated health care costs for an average individual with different health behaviours and socioeconomic positions. The annual sector-specific costs for an average individual were calculated by taking the primary attribution model estimates of the 2013/14 CCHS population and dividing by the number of individuals aged 25 and older in the CCHS cycle. This calculation was repeated using counterfactual 2013/14 CCHS population estimates where all individuals had been recoded to alternate exposures of health behaviours (all healthy or all unhealthy), or socioeconomic position (all high or all low), or combinations of both (all healthy and high socioeconomic position or all unhealthy and low socioeconomic position). To provide estimates calibrated to 2013/14 health care spending, the relative difference in sector-specific individual costs obtained in the counterfactual scenarios were centred around actual 2013/14 per capita estimates of sector-specific costs.

The burden of health care costs attributable to health behaviours and socioeconomic position

Total health care sector costs for individuals aged 25 and older were estimated by comparing ICES estimates of population health care spending to public accounts. For each fiscal year, sector-specific adjustment was performed to account for the underestimation of health care costs calculated at ICES. The result was sector-specific health care costs for each fiscal year that reflected actual government spending. For the 'other' category, health care costs associated with individuals aged 25 and older were estimated using the distribution of health care spending by age within the health care sector costs calculated at ICES. Annual estimates of attributable costs to health behaviours were calculated from 2003/04 to 2013/14 by combining these annual estimates of health care sector costs with their corresponding sector-specific PAFs and summing the results of the health care sectors together.

Estimating costs attributable to changes in health behaviours

The change in health care costs attributable to the change in health behaviours was estimated for 2004/05 to 2013/14. A baseline PAF for total health care costs to all health behaviours was estimated for 2003/04 using the previously derived PAFs and attributable costs. The overall health care budget was estimated over the subsequent decade assuming that health behaviours in 2003–2004 remained constant (e.g., the baseline PAF did not change over time). The difference between this counterfactual health care budget and the actual health care budget in each year provided an annual estimate of the change in health care costs attributable to the change in health behaviours.

Because of study limitations, we were not able to estimate attributable cost according to change in socioeconomic position.

Sensitivity analysis

We performed three sets of sensitivity analyses. First, we assessed health care costs and burden estimates by considering progressively more adjustment with risk factors other than age, sex and health behaviours (Model 1), basic sociodemographic characteristics (Model 2), additional sociodemographic characteristics (Model 3), health status mediators (Model 4) and fragility (Model 5). The estimate derived from Model 3 was assumed to be the most accurate and appropriate estimate of the attributable burden due to health behaviours. The estimates derived from Model 1 (simply age and behaviours) and Model 5 (the over-adjusted model) were used as upper and lower bounds of uncertainty. Second, we compared the age-standardized cost ratios after excluding the top 5% of health care users. Lastly, we used an alternative estimation approach, inverse propensity-weighted analyses, to assess the robustness of our health care cost ratios attributable to smoking derived from our main analyses. The inverse propensity-weighted analyses included several covariates ([Exhibits A-18 to A-33](#) in the Appendix), in addition to the original set used in the multivariate approach. The robustness of the health care cost ratios attributable to smoking was also evaluated by repeating these two methodologies across different smoking exposure classifications ([Exhibits A-34 and A-35](#)).

Online Calculator

We created an online calculator that estimates health care costs for individuals based on their customizable health profiles (available at www.projectbiglife.ca). The purpose of the calculator is to provide users with an interactive tool to further explore the factors that contribute to health care costs. The calculator uses Model 5, which contains all predictors including health mediators and fragility. This model allowed for the greatest discrimination, defined as the ability to differentiate between individuals at high risk and those at low risk.¹⁶ This model was not developed for causal or attributable uses. Accordingly, the proportion of health care costs that is attributable to health behaviours cannot be directly obtained from this model. Importantly, the calculator estimates the average health care costs for the entered health profile; the actual costs are wide ranging.

Limitations and Interpretive Cautions

In general, our study approach will underestimate the actual burden of health care costs attributable to the four health behaviours in Ontario. We note several limitations and cautions in interpreting the findings.

Children and adolescents were excluded

The study excluded individuals younger than 25 years of age. In general, health care costs for this age group are low. That said, alcohol burden for young people is a notable omission. Alcohol use is an important attribution of injury, suicide and other social burdens that occur disproportionately among the young.

Health risks were likely under-reported

The study used self-reported exposure to health risks, which generally results in an underestimation of risk burden, especially for diet and alcohol.¹⁷⁻²⁰ Survey respondents tend to over-report what they perceive as healthy behaviour and under-report unhealthy behaviour—this is referred to as social desirability bias.²¹ For example, in Ontario the sum of self-reported alcohol consumption is about half the volume of alcohol sold.²² Reporting accuracy affects all risks examined in this study. Estimates of burden are most affected when people report they are in the healthiest category (e.g., non-smoker or moderate drinker) when they are actually in an unhealthy category.

Similarly, respondents were asked brief questions about risks that may not capture the full spectrum of behaviour. For example, the study's measure of physical activity considered only leisure time physical activity; not included were active transportation (such as walking and bicycling to work), activity at work and sedentary time (time spent sitting). Our measure of diet was based on fruit and vegetable consumption

without specifically ascertaining the intake of sodium, trans fats and calories, and other aspects of healthy and unhealthy eating. In the case of trans fats, Canadian average intake was estimated to have reduced by 60% from the mid-1990s to 2008.²³

Furthermore, we used respondents' answers to health behaviours and other risks that correspond to their health behaviour at the time of the survey. Studies that consider lifetime changes in risks generate higher burden estimates. An exception is the burden estimates for physical activity, which may be overestimated due to reverse causality; that is, ill health is the cause of reduced physical activity.

Other health care costs were estimated indirectly

Costs associated with outpatient clinic visits in hospital settings (e.g., ambulatory orthopaedic or ophthalmology clinic visits) were not included in the ICES health care cost data. Prior to 2006, these exclusions also included dialysis and oncology outpatient visits. These clinic visits account for an average of 15%–17% of all acute care costs. Health care system operating costs and capital costs are also not included in the ICES health care cost data; however, as previously outlined, the final cost analyses were adjusted to consider these costs.

Findings

The population attributable fractions for the four behavioural risks were calculated using responses from 80,749 Ontarians surveyed between 2003 and 2008. In total, there were 312,952 person-years of follow-up (**Exhibit A-3** in the Appendix). After adjusting for age, we observed increased health care cost ratios for all health behaviours (smoking, unhealthy alcohol consumption, poor diet and physical inactivity). With the exception of heavy alcohol consumption, the increase was observed in both sexes across all three health care sectors examined: hospital care, drugs and community care (**Exhibits A-4 to A-11**).

The Evidence

Health care use for Ontarians with different levels of risk exposure

Exhibit 2 shows health care expenditure in 2013 for Ontarians with exposure to unhealthy behaviours (heavy smoking, heavy drinking, very poor diet and physically inactive) compared to those with healthy behaviours (no smoking, moderate drinking, adequate diet and physically active), Ontarians with low socioeconomic position (less than high school completion, a household income of \$29,999 or less, no home ownership and high neighbourhood

deprivation) compared to high socioeconomic position (post-secondary school graduate, household income of \$80,000 or more, a residence owned by a household member and low neighbourhood deprivation), and Ontarians with both unhealthy behaviours and low socioeconomic position compared to those with healthy behaviours and high socioeconomic position.

Hospital care costs showed the widest variation, followed by community care costs; there was minimal variation for drug costs. Individuals with exposure to all health behaviour and socioeconomic position risks had annual hospital care costs that were more than 400% higher than those of individuals with healthy behaviours and high socioeconomic position (\$5,796 versus \$1,152).

There was a consistent dose-response such that individuals with poor health profiles had higher health care costs. For example, current heavy smokers (one or more packs of cigarettes per day) had the highest level of health care costs followed by former heavy smokers, light smokers, former light smokers and non-smokers. The three other risk factors—alcohol, diet and physical activity—showed similar dose-response relationships. Furthermore, people with multiple health behaviour risks had higher health care use than people with one health behaviour risk. Previous research focused on high health care users; our research looked at the total population and then at the population with high health care users excluded. We found a gradient for higher health care use for those with worse health behaviours in both groups i.e., irrespective of whether they were a high health care user or not (**Exhibits A-4 to A-11** in the Appendix).

Health care use attributed to health behaviours

Exhibit 3 shows that from 2004 to 2013, 22% of Ontario's health care costs could be attributed to the four health behaviour risk factors. Physical activity had the largest attribution (13%), followed by smoking (10%). However, there was notable uncertainty in the burden estimates for physical activity and diet, with the potential for overestimation for physical activity and underestimation for diet. Alcohol-attributable health care costs were also likely underestimated (see the **Limitations** section).

Exhibit 4 shows the growth in annual health care expenditure from 2004 to 2013 for all of Ontario and for Ontarians aged 25 and older (the focus of this study). In 2013, health care costs for Ontarians aged 25 and older totalled \$44.2 billion (89% of the total \$49.9 billion expenditure). During the 10-year period from 2004 to 2013, \$89.4 billion in health care costs were attributable to health behaviours (**Exhibit 5**). In that same period, the costs attributable to health behaviours improved by nearly 2% (from 23.3% in 2004 to 21.4% in 2013). If the proportion of health care expenditure that can be attributed to health behaviours (the population-attributable fraction) had remained at 23.3%, use of health care would have been \$4.9 billion greater (what we term the avoided cost).

Population health impact of behavioural risks

Exhibit 6 presents the burden of health behaviours related to health care costs (\$89.4 billion) and the costs avoided by the adoption of healthy behaviours (\$4.9 billion). Physical inactivity and smoking contributed the largest proportion of the burden (53% and 41%, respectively). However, a decline in smoking between 2004 and 2013 was responsible for 84% of the avoided costs. Exhibit 7 presents health behaviour-attributable costs by health care sector. Costs related to hospital care account for the largest portion of the burden at 46%, community care costs account for 22% and drug costs for 11%; the remaining 21% is accounted for by other health care costs.

The three scenarios from our sensitivity analysis demonstrate results that are similar to our main

analysis. As previously indicated, excluding high-cost health care users demonstrated slightly attenuated cost ratios for men and women (**Exhibits A-4 to A-11** in the Appendix). Not unexpectedly, the attribution of health care costs to health behaviours decreased as we increased the number of risk factors adjusted for in the model (**Exhibits A-12 to A-17**). The inverse propensity-weighted model, which adjusted for additional variables, had similar cost ratios to the base health behaviour multivariable model (**Exhibits A-34** and **A-35**).

Health care use attributed to socioeconomic position

Between 2004 and 2013, \$60.7 billion in health care costs were attributable to low socioeconomic position (**Exhibit 8**). When health behaviours and socioeconomic position are considered jointly, the health care cost burden was \$134 billion. **Exhibit 9** presents the burden associated with socioeconomic position by health care sector. Compared to the health behaviour analysis, a larger portion of the burden is due to hospital care costs (54%); community care costs account for 19% of the burden, drug costs account for 9%, and the remaining 18% is accounted for by other health care costs.

The Study in Context

Several studies have evaluated the economic burden of individual behavioural risk factors, but very few have evaluated the simultaneous impact of multiple risk factors. These latter studies have used traditional population attributable fraction methods to estimate economic burden.²⁴⁻²⁷ Briefly, these methods identify diseases where health behaviours are risk factors, estimate the health care costs of these diseases, calculate the proportion of the disease that can be attributed to the risk factors (based on relative risk of disease from an external source and prevalence of exposure in the population of interest), and apply these population attributable fractions to the cost data. There are limitations associated with these methods that stem from combining ecological summary measures of exposure, outcome and hazards across different sources of data.²⁸

The use of multivariable algorithms and the direct attribution of health behaviours to health care costs offer several advantages over analyses that have been performed to date. These include controlling for confounders, accounting for complexities in the relationship between multiple exposures and covariates, using consistent definitions of exposure, and using specific measures of risk derived internally from the study population. Additionally, to our knowledge, this is the first study to examine health care costs using both multivariable and propensity-weighted approaches.

Discussion

This study shows that a considerable reduction in health care expenditure in Ontario has been achieved through changes in health behaviours. The premium derived from improved health behaviours equates to a 1.9% reduction in health care expenditure over the 10-year period from 2004 to 2013. At first glance, a 1.9% improvement may seem small; however, given the magnitude of the province's health care expenditure, it amounts to a not-insignificant \$4.9 billion. We are not aware of other health interventions or strategies that have led to as large a reduction in expenditure as those reported in this study.

In total, we found that 22% of Ontario's health care costs could be attributed to health behaviours. This equates to more than \$89.4 billion over the 10-year period from 2004 to 2013. Socioeconomic

position contributed 15%, or \$60.7 billion, to the province's health care costs. Taken together, health behaviours and socioeconomic position contributed to a burden of \$134 billion in health care costs. These calculations are likely conservative or underestimated due to study limitations (for examples, refer to earlier comments related to the assessment of healthy eating and the exclusion of data on youth alcohol use). The large remaining burden from health behaviours and social inequalities suggests that there are significant opportunities to further reduce health care expenditures through population health strategies.

This study confirms our previous analyses, which showed that health behaviours are an important contributor to poor health.^{1,29} As with our previous study, we found that most costs are associated with

hospital care, which, for the most part, seeks to maintain or restore health to people with significant illness or disability. Therefore, in addition to the benefit of cost savings, preventing hospital use can be equated with preventing health-limiting illness or disability.

There is mounting discourse about health system sustainability in the face of rising health care costs; missing from the debate is a discussion about contributors to reduced health care expenditures. For example, each year the Canadian Institute for Health Information publishes a report on health care expenditure trends. The report includes analyses and a discussion on what is responsible for increasing expenditures but does not include a counterview on what is responsible for decreasing them. References

to the “aging crisis” and the “silver tsunami” are common examples of the pessimistic outlook regarding health system sustainability; 61% of Canadians doubt that “the country’s hospitals and long-term care facilities will be able to meet the demands of Canada’s relentlessly aging population.”^{30,31} Our study provides a more optimistic outlook. In the 10-year period coinciding with our investigation, population aging resulted in a 0.9% annual increase in health care expenditure with a modest projected annual increase of 1.1% to 2030.^{14,32} Viewed comparatively, over the study period there was a 9% increase in health care expenditure due to population aging and a 1.9% decrease in expenditure from improving health behaviours. In other words, for every \$1 increase in health care expenditure due to aging, there was a 21¢ reduction in expenditure from improving health behaviours. (Again, due to study limitations the reduction is likely conservative and does not include reductions due to change in socioeconomic position).

Another notable point about aging and health behaviours: while aging is inevitable, health behaviours (and social inequities) are modifiable. Reduced smoking was the main contributor to avoided health care costs from health behaviours (accounting for 88% of the 1.9% cost reduction, or 1.7% in total). This large cost reduction is a reflection of Ontario’s successful smoking prevention strategy. To date, improved diet and physical activity have made only small contributions to reduced costs, reflecting little improvement in these health behaviours in Ontario and the lack of a comprehensive strategy such as *Smoke-Free Ontario*.

In our 2009 ICES report, *What Does It Take to Make a Healthy Province?*, we recommended that

Ontario adopt health behaviour targets that were at least as ambitious as British Columbia’s.³³ We also outlined recommendations on how to achieve those targets. Separately, we estimated that achieving British Columbia’s health behaviour targets would result in an Ontario life expectancy increase of three years.²⁹ The savings to the Ontario health care system would be similarly large.

Our study shows the importance of integrating public health programming and prevention efforts within the health care system—a key feature of the current health strategy in the *Patients First* initiative, which emphasizes better coordinated delivery of health care within the province’s 14 Local Health Integration Networks.^{34,35} A greater investment in disease prevention and population health could help increase the sustainability of health care by reducing spending on illness, in particular with respect to hospital care. Combining this effort with strategies that address social determinants of health can reap further benefits.

Indeed, our study suggests that interventions outside the health care system, such as improving levels of income and education and other factors that influence socioeconomic position, will reduce health care expenditures. It has been recognized that the health system is but one determinant of population health and that more attention must be paid to the needs of disadvantaged individuals, populations and communities in order to avoid increasing health disparities.³⁷ While health inequities play a significant role in health system costs, estimating the cost of the gap in health care as a result of socioeconomic position can be difficult because of the complexity of the problem. Our study is one of the few that has

been able to translate this gap into a dollar figure. In building a disparities perspective into our examination of the contribution of health behaviours and other risks to health care costs, we have advanced a more comprehensive approach to reducing health inequities. With direct health care spending/costs/expenditures in Canada growing, there is potential to negatively impact investment in other areas that are critical to improving health (e.g., education, public housing, income security³⁶), especially for those who are most marginalized.

Amid concerns over rising health care costs, attention has focused on high-cost users of health care.³⁷⁻³⁹ Our study shows the wide variation in health care costs for individuals with favourable versus unfavourable health behaviours and socioeconomic profiles. Better health and well-being is the primary goal of improving health behaviours and reducing social inequity. However, it is important to recognize that the existing investment in public health also results in a large reduction in expenditure in the acute care sector, particularly hospital care. The health premium of prevention and social equity is an overlooked opportunity for a sustainable health care system.

Exhibits

EXHIBIT 1 Definitions of behavioural health risks

Behaviour	Category*	Definition
Smoking	Heavy smoker	Current daily smoker (≥ 20 cigarettes/day)
	Light smoker	Current daily smoker (< 20 cigarettes/day) or current occasional smoker with ≥ 100 lifetime cigarettes
	Former heavy smoker	Former daily smoker (≥ 20 cigarettes/day)
	Former light smoker	Former daily smoker (< 20 cigarettes/day) or former occasional smoker with ≥ 100 lifetime cigarettes
Alcohol	<i>Non-smoker</i>	<i>Never smoker or occasional smoker <100 lifetime cigarettes</i>
	Heavy drinker	Bingeing[†] or ≥ 21 (men) or ≥ 14 (women) drinks/week
	<i>Moderate drinker</i>	<i>≤ 21 (men) or ≤ 14 (women) drinks/week with no bingeing[†]</i>
	Current non-drinker	No alcohol consumption in the last 12 months
Diet	Very poor diet	Index score 0 to < 2.5
	Fair diet	Index score 2.5 to < 5
	<i>Adequate diet</i>	<i>Index score 5 to 10</i>
Physical activity	Inactive	0 to < 1.5 METs/day
	Moderately active	1.5 to < 3 METs/day
	Active	≥ 3 METs/day

*Highest risk levels are in boldface and lowest risk levels (reference group) are in italic.

[†]Bingeing was defined as ≥ 5 drinks/day on any day in the previous week or weekly bingeing behaviour in the previous month.

Index score = the healthiness of a diet based on consumption of fruit and vegetables. Individuals start with 2 points and are given up to 8 additional points for each average daily serving of fruits and vegetables (maximum score = 10). Points are deducted for daily fruit juice servings exceeding 1 (-2 points), no carrot consumption (-2 points), or daily potato consumption exceeding 1 serving for males and 0.7 servings for females (-2 points). Scores that result in negative values after deductions are recoded to zero, resulting in a final range of 0 to 10 for the index.

MET = metabolic equivalent of task, a measure of calories burned by type, duration and frequency of physical activity.

EXHIBIT 2 Annual health care costs for Ontarians aged 25 and older: unhealthy behaviour and low socioeconomic position versus healthy behaviour and high socioeconomic position, 2013

Key finding

- Compared to those with healthy behaviours and high socioeconomic position, Ontarians with all four behavioural risks and low socioeconomic position had annual hospital costs that were 403% higher (\$902 versus \$4,537).

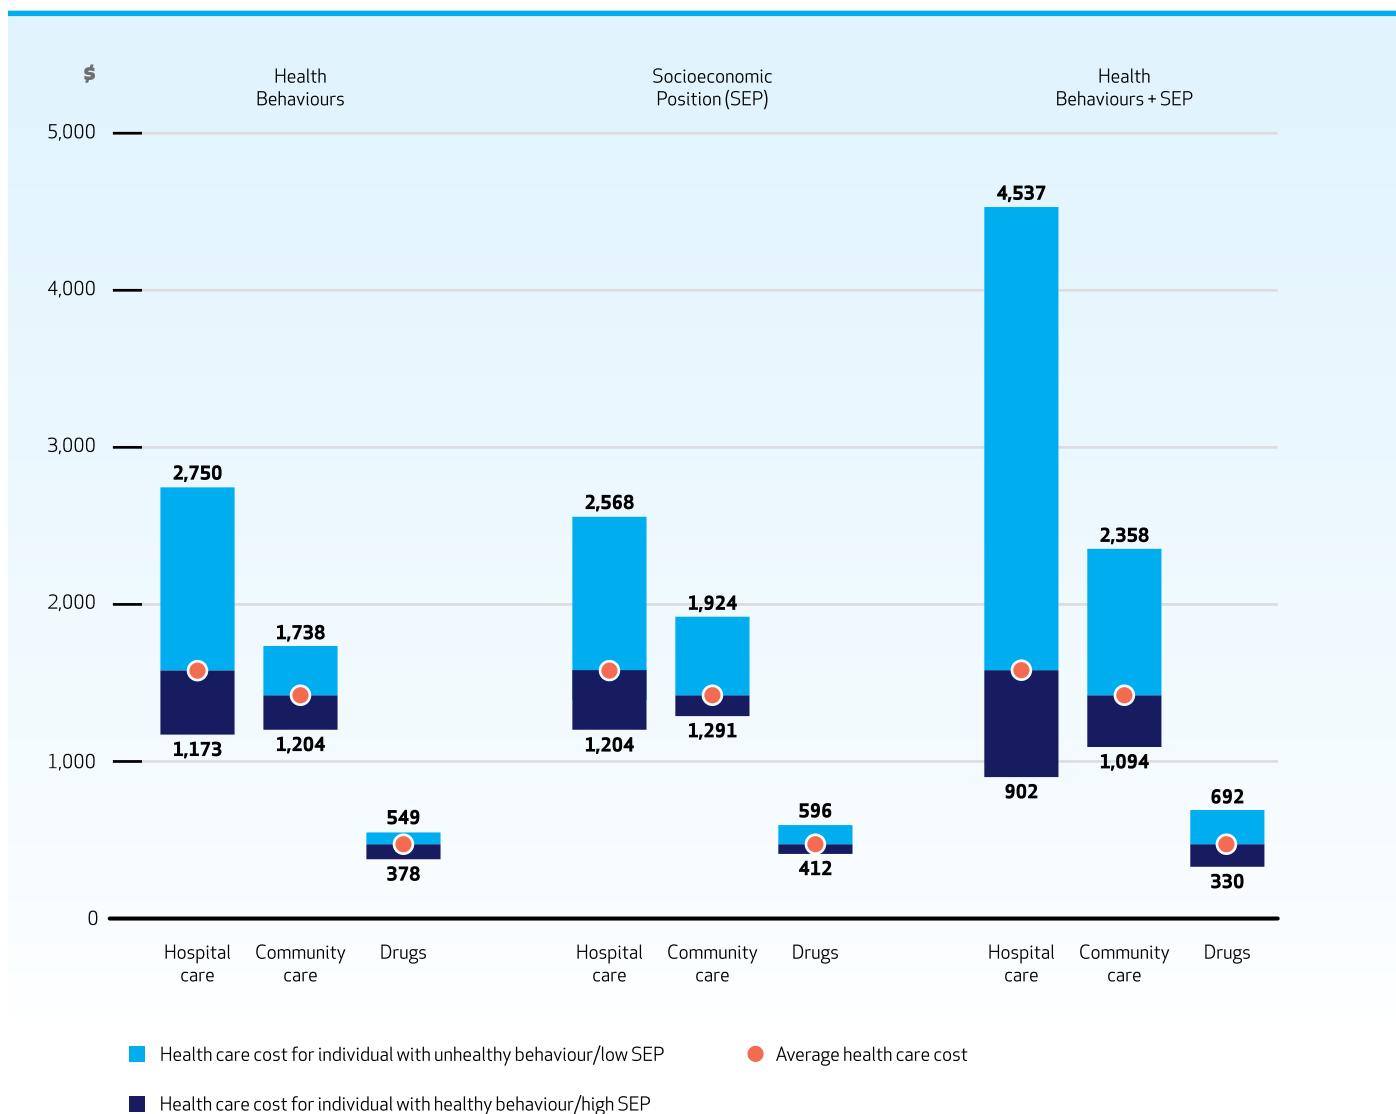

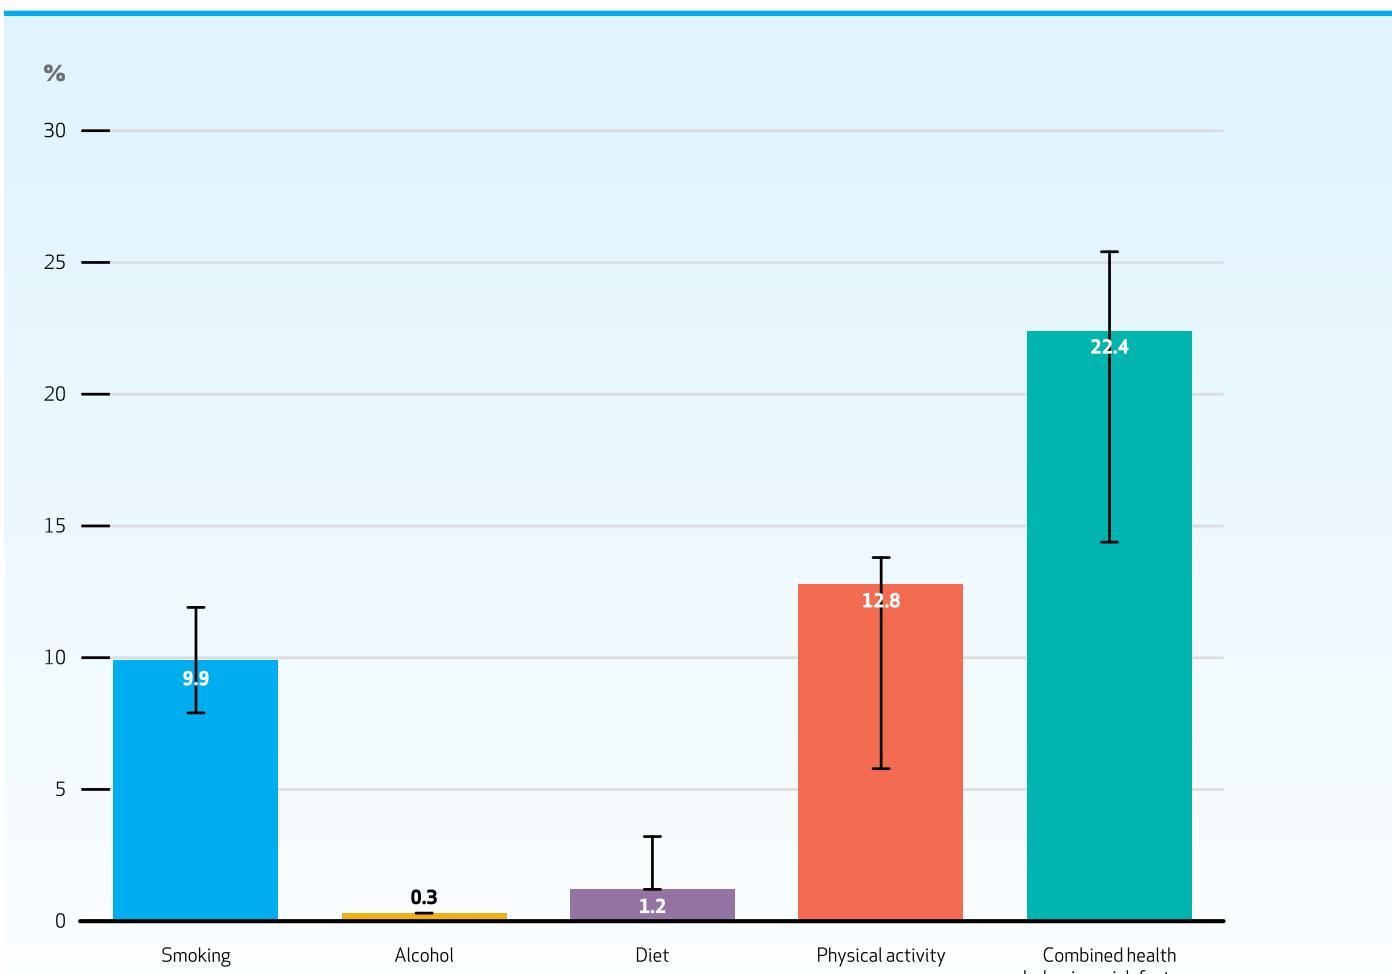

EXHIBIT 3 Proportion of health care costs attributed to selected health behaviour risk factors for Ontarians aged 25 and older, 2004 to 2013***Key findings**

- The four behaviour risk factors combined accounted for 22% of health care costs.
- Physical activity and smoking accounted for the largest proportion of total health care costs at 13% and 10%, respectively.

*Error bars represent high and low boundaries on burden estimates.

EXHIBIT 4 Annual health care costs for Ontario, 2004 to 2013***Key findings**

- Annual health care costs are large.
- Annual health care costs increased rapidly until 2009, after which inflation-adjusted costs stabilized.
- This study included 88% of total costs, reflecting health care for individuals aged 25 and older.

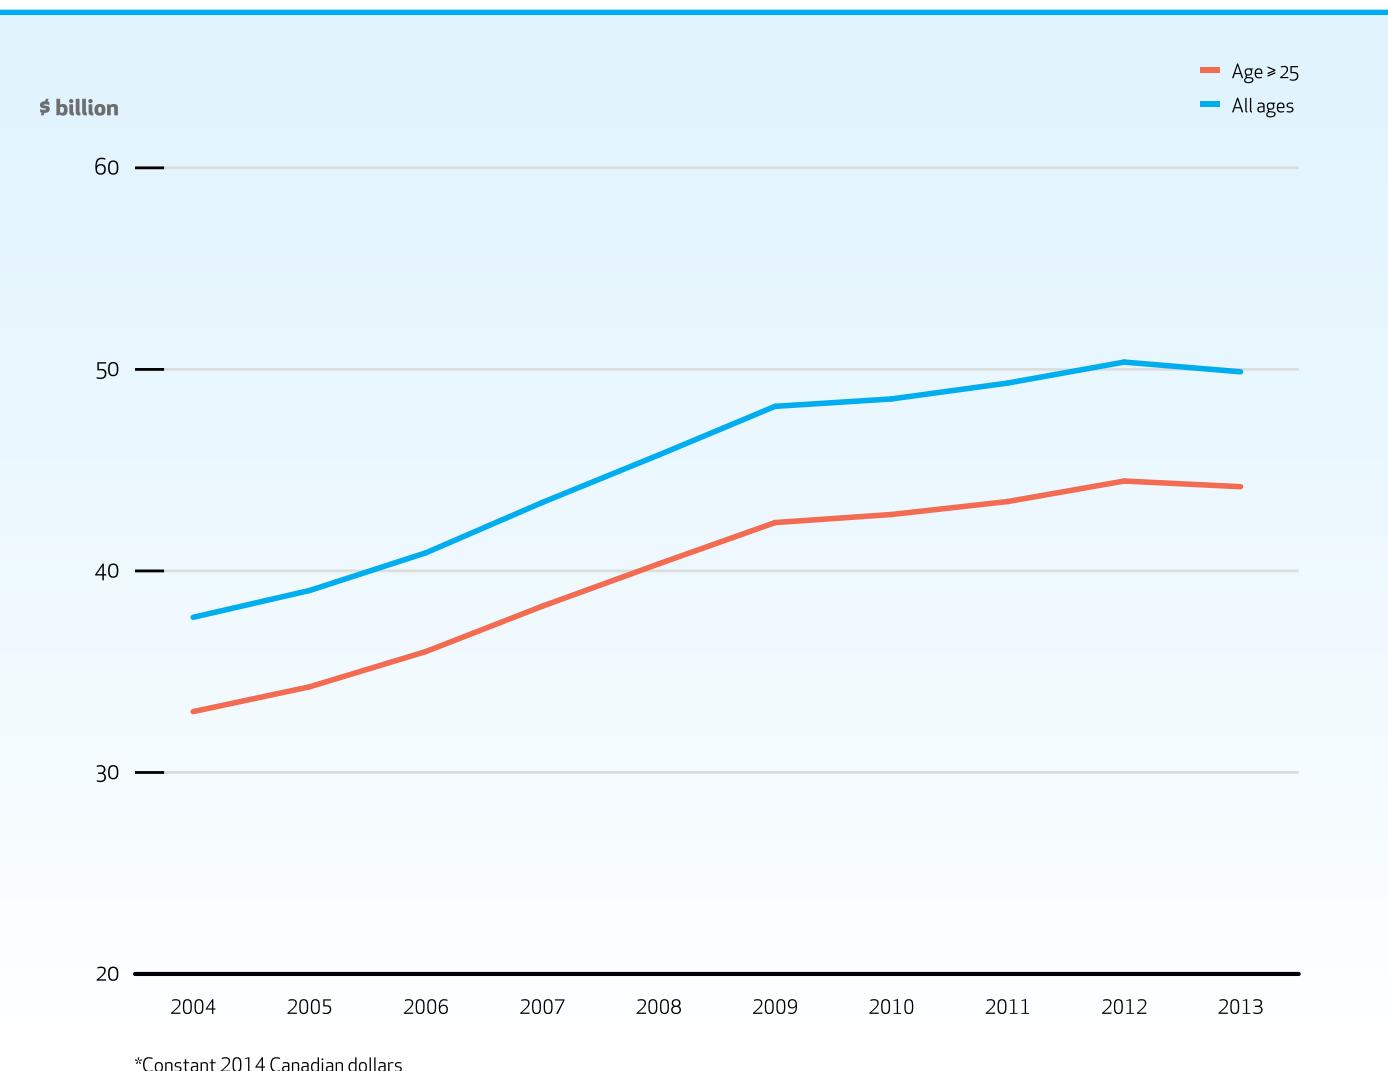

EXHIBIT 5 Burden of health behaviour risk factors on health care costs for Ontarians aged 25 and older, 2004 to 2013*

Key findings

- Overall, \$89.4 billion in health care costs from 2004 to 2013 could be attributed to health behaviours.
- Health behaviour-attributable use of health care improved over the 10-year period, declining from 23.3% to 21.4%. This improvement equates to a cumulative reduction in use that is equivalent to \$4.9 billion in health care costs.

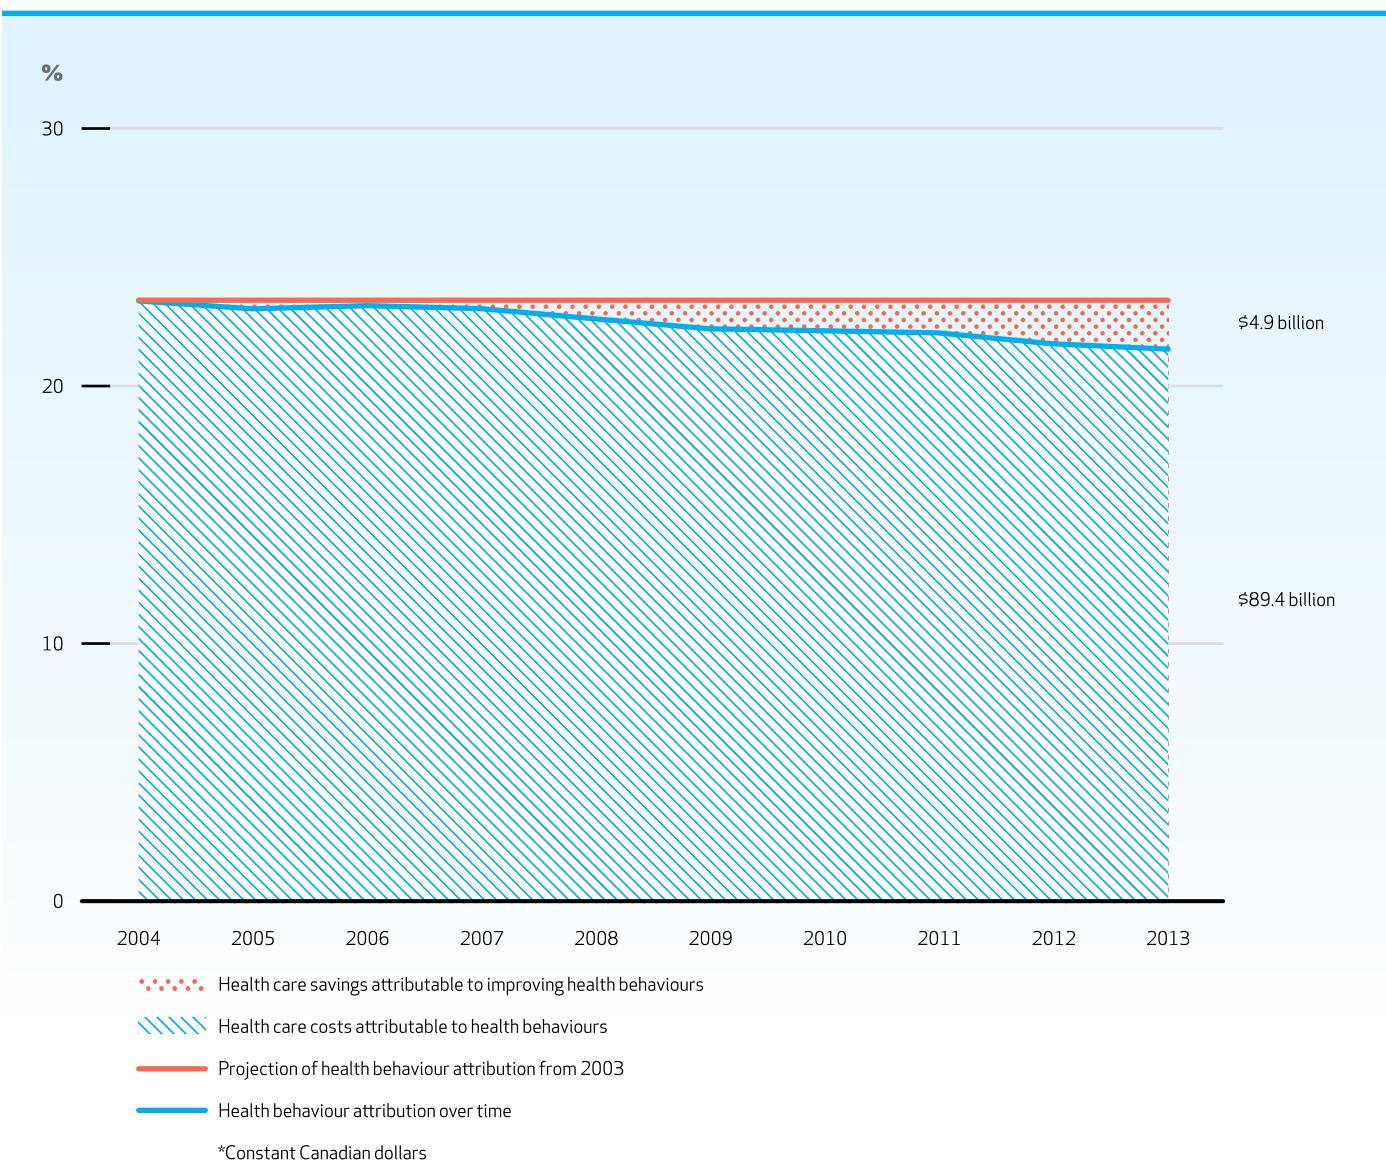

EXHIBIT 6 Health care attributable and avoided costs by health behaviour risk factor for Ontarians aged 25 and older, 2004 to 2013**Key findings**

- Physical activity and smoking were the leading health behaviours for attributable health care costs in Ontario between 2004 and 2013.
- The cost savings realized between 2004 and 2013 were primarily achieved through improvement in smoking-attributable costs.

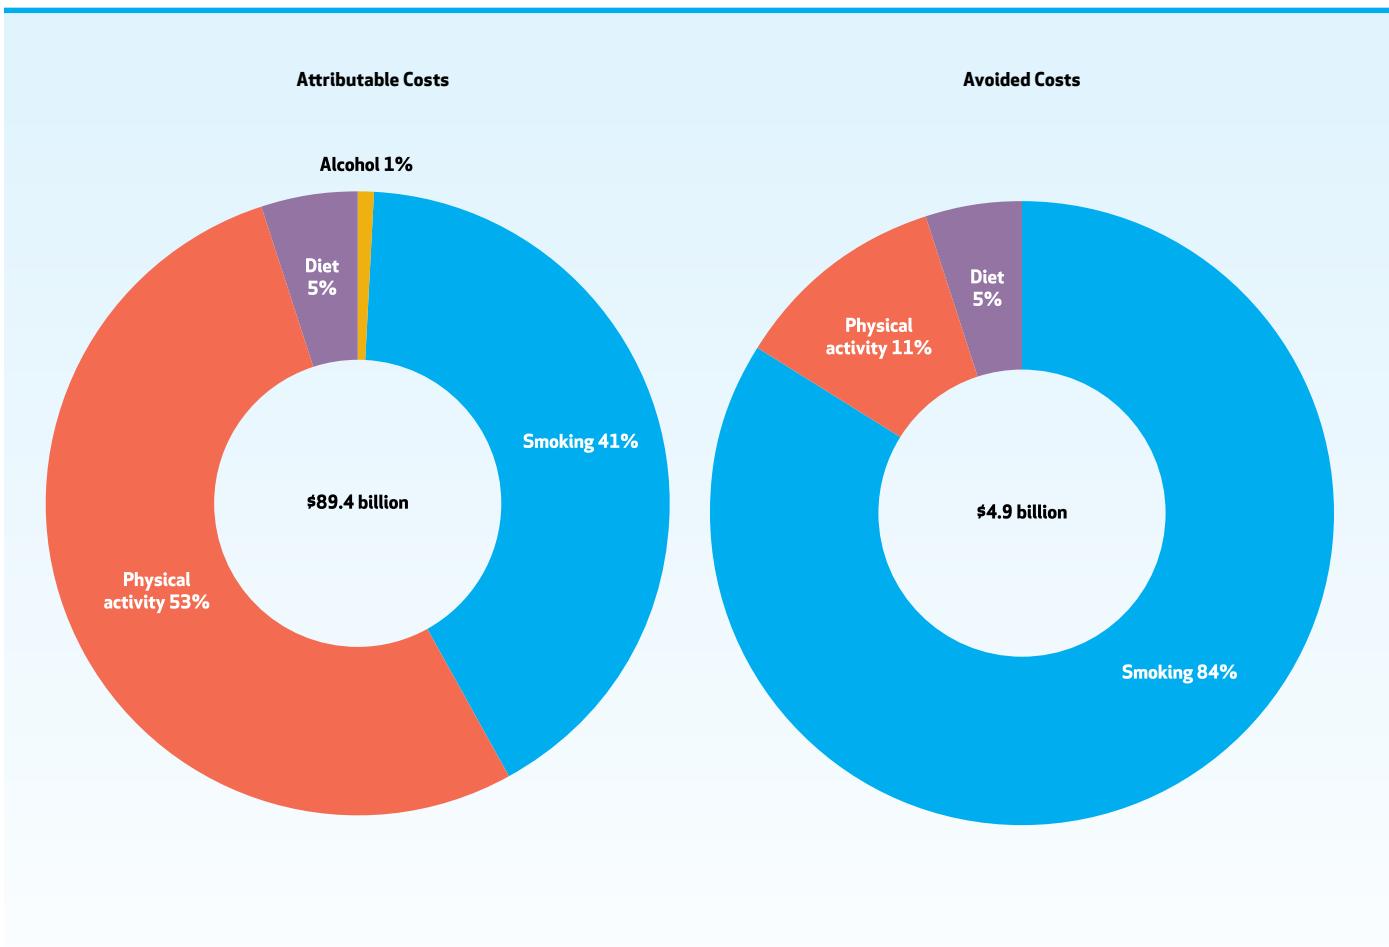

EXHIBIT 7 Health behaviour-attributable health care costs by sector for Ontarians aged 25 and older, 2004 to 2013**Key finding**

- Hospital care accounted for almost half of health behaviour-attributable health care costs between 2004 and 2013

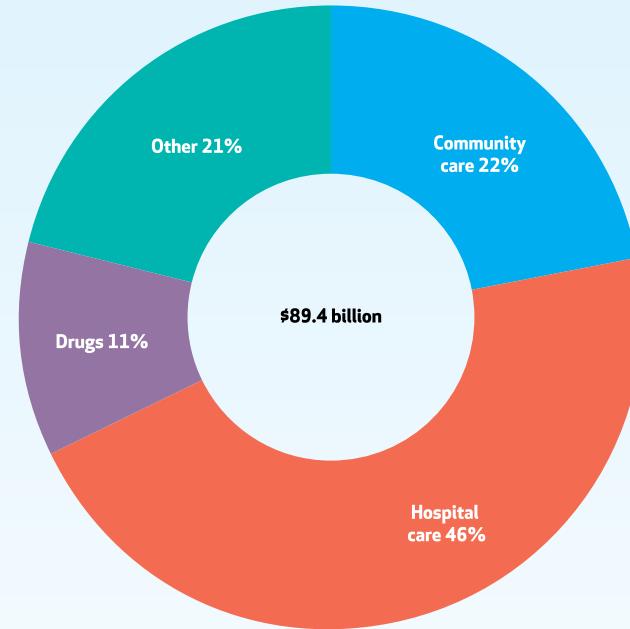

EXHIBIT 8 Health behaviour risk factors and socioeconomic position attribution to health care costs for Ontarians aged 25 and older, 2004 to 2013**Key findings**

- From 2004 to 2013, \$60.7 billion in health care costs were attributed to low socioeconomic position.
- Over the same period, \$133.9 billion in health care costs were attributed to the combined impact of health behaviours and low socioeconomic position.

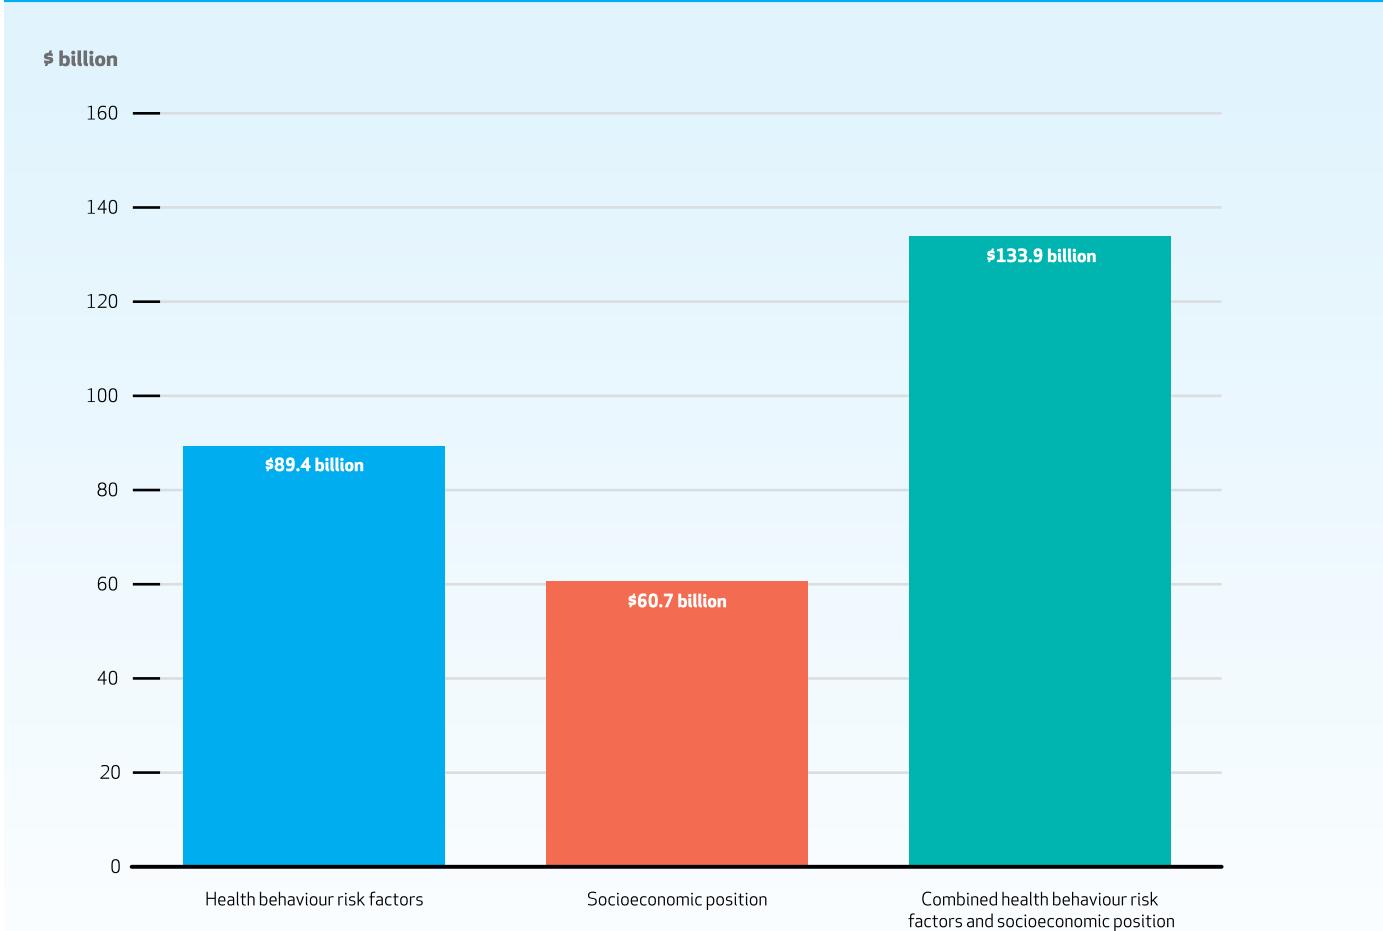

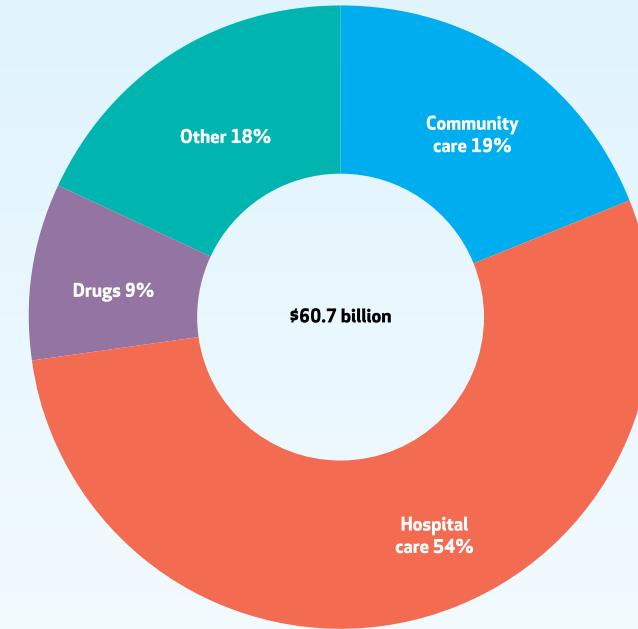

EXHIBIT 9 Socioeconomic position attribution to health care costs for Ontarians aged 25 and older, by sector, 2004 to 2013**Key finding**

- Hospital care accounted for more than half of the health care costs attributable to low socioeconomic position.

List of Exhibits

EXHIBIT A-1 Creation of Ontario study cohort

EXHIBIT A-2 Stepped approach to model building — consideration of factors leading to health care use and costs

EXHIBIT A-3 Baseline description of the study cohort by sex, 2003 to 2007

EXHIBIT A-4 Age-adjusted total health care cost ratios for Ontario men in a four-year period from 2004 to 2013

EXHIBIT A-5 Age-adjusted total health care cost ratios for Ontario women in a four-year period from 2004 to 2013

EXHIBIT A-6 Age-adjusted hospital care cost ratios for Ontario men in a four-year period from 2004 to 2013

EXHIBIT A-7 Age-adjusted hospital care cost ratios for Ontario women in a four-year period from 2004 to 2013

EXHIBIT A-8 Age-adjusted drug cost ratios for Ontario men aged 65 and older in a five-year period from 2004 to 2013

EXHIBIT A-9 Age-adjusted drug cost ratios for Ontario women aged 65 and older in a five-year period from 2004 to 2013

EXHIBIT A-10 Age-adjusted community care cost ratios for Ontario men in a five-year period from 2004 to 2013

EXHIBIT A-11 Age-adjusted community care cost ratios for Ontario women in a five-year period from 2004 to 2013

EXHIBIT A-12 Hospital care cost ratios for the male cohort, by model

EXHIBIT A-13 Hospital care cost ratios for the female cohort, by model

EXHIBIT A-14 Drug cost ratios for the male cohort aged 65 and older, by model

EXHIBIT A-15 Drug cost ratios for the female cohort aged 65 and older, by model

EXHIBIT A-16 Community care cost ratios for the male cohort, by model

EXHIBIT A-17 Community care cost ratios for the female cohort, by model

EXHIBIT A-18 Inverse propensity-weighted comparison of non-smokers and heavy smokers in the male cohort

EXHIBIT A-19 Inverse propensity-weighted comparison of non-smokers and heavy smokers in the female cohort

EXHIBIT A-20 Inverse propensity-weighted comparison of non-smokers and light smokers in the male cohort

EXHIBIT A-21 Inverse propensity-weighted comparison of non-smokers and light smokers in the female cohort

EXHIBIT A-22 Inverse propensity-weighted comparison of non-smokers and former heavy smokers in the male cohort

EXHIBIT A-23 Inverse propensity-weighted comparison of non-smokers and former heavy smokers in the female cohort

EXHIBIT A-24 Inverse propensity-weighted comparison of non-smokers and former light smokers in the male cohort

EXHIBIT A-25 Inverse propensity-weighted comparison of non-smokers and former light smokers in the female cohort

EXHIBIT A-26 Inverse propensity-weighted comparison of non-smokers and heavy smokers aged 65 and older in the male cohort

EXHIBIT A-27 Inverse propensity-weighted comparison of non-smokers and heavy smokers aged 65 and older in the female cohort

EXHIBIT A-28 Inverse propensity-weighted comparison of non-smokers and light smokers aged 65 and older in the male cohort

EXHIBIT A-29 Inverse propensity-weighted comparison of non-smokers and light smokers aged 65 and older in the female cohort

EXHIBIT A-30 Inverse propensity-weighted comparison of non-smokers and former heavy smokers aged 65 and older in the male cohort

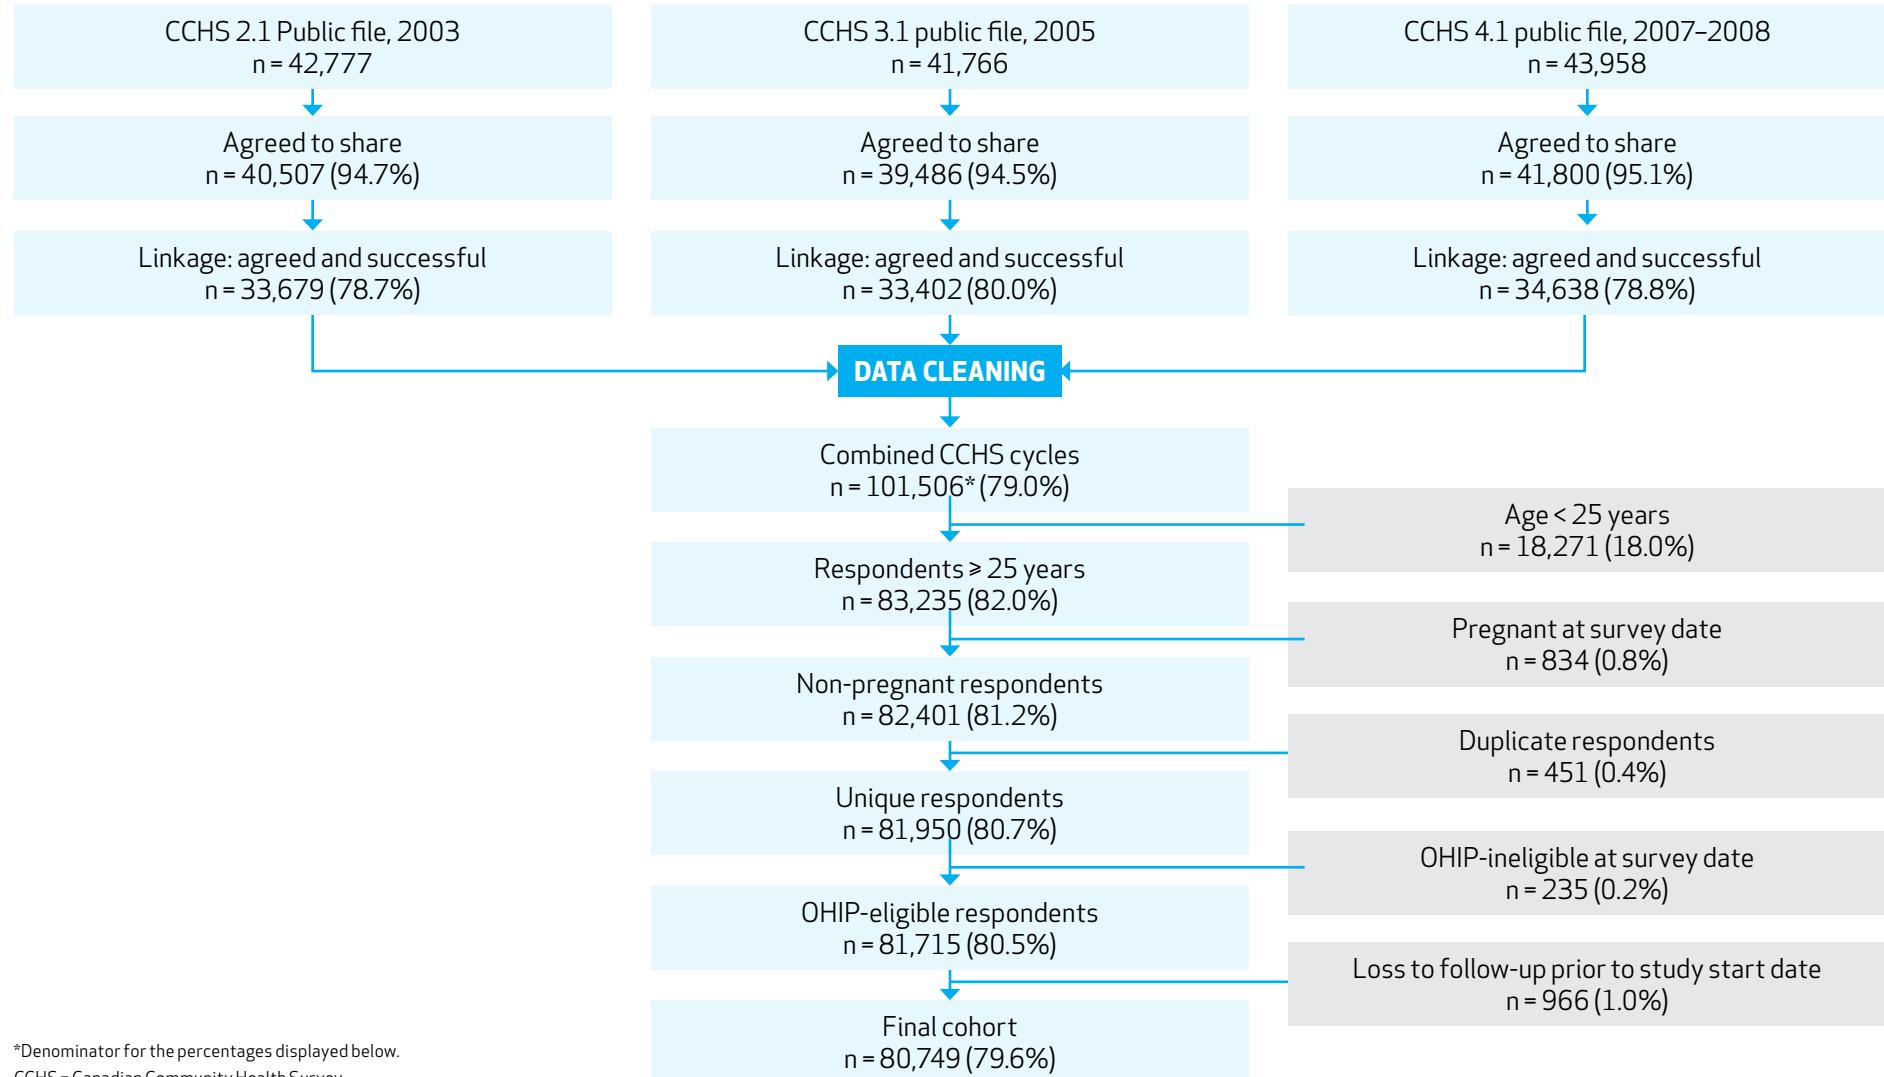

EXHIBIT A-31 Inverse propensity-weighted comparison of non-smokers and former heavy smokers aged 65 and older in the female cohort

EXHIBIT A-32 Inverse propensity-weighted comparison of non-smokers and former light smokers aged 65 and older in the male cohort

EXHIBIT A-33 Inverse propensity-weighted comparison of non-smokers and former light smokers aged 65 and older in the female cohort

EXHIBIT A-34 Health care cost ratios — comparison of multivariable and inverse propensity-weighted models by cohort sex

EXHIBIT A-35 Health care cost ratios — comparison of multivariable and inverse propensity-weighted models by cohort sex, sensitivity analysis

^aFollow-up years two to five for respondents to the Canadian Community Health Surveys conducted in 2003, 2005 and 2007-2008.

^bHealth care costs per person-year, age-adjusted using the 1991 Canadian standard population.

^cIncludes self-employment.

^dCost ratios could not be obtained because the majority of the cohort were aged 35 and older.

EXHIBIT A-8 Age-adjusted drug cost ratios for Ontario men aged 65 and older in a five-year period from 2004 to 2013*
